Fifteen years following the first discoveries^{1,2}, more than 200 extra solar planet (exoplanet) candidates are known. Most of them are hosted by core hydrogen burning main sequence stars similar to our Sun, although a few planets orbiting red giant stars have been recently found³. When their core hydrogen runs out, main sequence stars undergo a red giant expansion that modifies the planetary orbits and can easily reach and engulf the inner planets. The same will happen to the planets of our solar system in about 5 Gyr and the fate of the Earth is matter of debate^{4,5}. Here we report the discovery of a planetary-mass body ($M \sin i = 3.2 M_{JUP}$) orbiting the extreme horizontal branch, core helium burning, pulsating star V 391 Pegasi at a distance of about 1.7 astronomical units (AU), with a period of 3.2 yr. The maximum radius of the red giant precursor may have

reached 0.7 AU, whereas the orbital distance of the planet during the stellar main sequence phase is estimated to be about 1 AU. This first detection of a planet around a post-red giant star proves that planets with orbital distances < 2 AU can survive the red giant expansion.

With an effective temperature close to 30,000 K and a surface gravity 10 times solar⁶, V391 Pegasi (or HS 2201+2610 from the original Hamburg Schmidt survey name) is one of \sim 40 hot subdwarf B (sdB) stars showing short period p-mode pulsations⁷. Its pulsational spectrum exhibits four or five pulsation periods between 342 and 354 s^{6,8}. More details on the star's properties are given in the online Supplementary Information.

Because of their compact structure, sdB pulsators have extremely stable oscillation periods, like white dwarf pulsators. It is therefore possible to register very small differences in the arrival times of the photons^{9,10}, which in principle allows the detection of low-mass secondary bodies¹¹, through use of the Observed – Calculated (O–C) diagram¹² (see caption of Fig. 1 for more details). Functionally, it is equivalent to the timing method used to find planets around pulsars^{1,13}.

When a pulsation period changes linearly in time, the O–C diagram has a parabolic shape, as confirmed by all the previous measurements of dP/dt

(or \dot{P}) in compact pulsators^{9,14,15}. The same behaviour is found in the O–C plot of V 391 Peg (upper panel of Fig. 1), implying that the main pulsation period of the star is increasing at a rate of $\dot{P}_1 = (1.46 \pm 0.07) \times 10^{-12}$ (or 1 s in 22,000 yr).

For V 391 Peg a simple second-order polynomial does not give a satisfactory fit and the sinusoidal residuals require further interpretation (lower panel of Fig. 1). An oscillating \dot{P} is not compatible with any evolutionary or pulsational model: it would require that the star expands and contracts periodically every 3 years, a time much larger than the dynamical time-scale, which is of the order of 500 s for an sdB star. Nor can the sinusoidal residuals be explained by any known pulsational effect. Random period variations¹⁶ are also not a possibility because these variations would be cancelled by the large number of pulsation cycles (>28 for each point in Fig. 1).

The simplest explanation for the sinusoidal component of the O–C diagram in Fig. 1 is a wobble of the star’s barycentre due to the presence of a low-mass companion. Depending on its position around the barycentre of the system, the sdB star is periodically closer to, or more distant from us by 5.3 ± 0.6 light seconds and the timing of the pulsation is cyclically advanced or delayed. From our best fit and Kepler’s third law (assuming a circular orbit, $M_1 = 0.5 M_\odot$, M_\odot being the mass of the Sun, and $M_2 \ll M_1$), we obtain:

$P_{\text{ORB}} = 1,170 \pm 44$ d (or 3.20 ± 0.12 yr), $a \simeq 1.7$ AU, $M_2 \sin i \simeq 3.2 M_{\text{JUP}}$, where a is the planet-star separation and 1 AU (Astronomical Unit) is the mean distance between Earth and Sun. This interpretation is robust: the same sinusoidal component is also found in the O–C diagram of the secondary pulsation frequency of the star (see Figs 2 and 3 for more details). Any alternative interpretation of our results would have to be compatible with this fact. The sinusoids in the lower panels of Figs 1, 2 and 3 suggest a circular orbit. From our observations we cannot yet set a precise upper limit to the eccentricity, but it must be close to zero.

Using the known characteristics of the V 391 Peg system, we can determine a first estimate of the planet's effective temperature by balancing the flux received from the star with the black-body flux re-radiated by the planet (see online Supplementary Information for more details). Assuming a Bond albedo of 0.343 (similar to Jupiter¹⁷), we obtain an effective temperature for the planet of about 470 K, corresponding to a maximum of the black-body radiation near $6.2 \mu\text{m}$ from Wien's law.

With a projected radius of ~ 5 light seconds, the wobble of the barycentre of V 391 Peg points towards a planet (the amplitude of the Solar displacement around the barycentre of the solar system is almost 3 light seconds). However, depending on the unknown inclination i of the system, a brown dwarf or

even a low-mass stellar companion can not be totally excluded. But the low inclination required ($2.5^\circ \lesssim i \lesssim 14^\circ$ or $i \lesssim 2.5^\circ$) has a very low probability (3% and 0.1% respectively), assuming a random distribution of orbital plane inclinations.

Thus, with a 97% probability, V 391 Peg b is the first planet orbiting a post-red giant star, making this system a unique laboratory to test the evolution of the planetary systems during and after the red giant expansion. With a probable age of the order of 10 Gyr (see online Supplementary Information for more details), V 391 Peg b is also one of the oldest planets known. An interesting case of a brown dwarf that survived the engulfment by a red giant was recently presented¹⁸; the information about the survivability of low-mass companions to red giant stars given by that system is complementary to that of V 391 Peg, the two systems being very different. Note that only by studying planets of horizontal branch stars it is possible to isolate the effects of the red giant expansion on a planetary system. Planets around white dwarfs must be strongly modified also by the asymptotic giant branch expansion, the thermal pulses and the final planetary nebula ejection¹⁹.

Even though, in terms of orbit stability, the existence of V 391 Peg b is not surprising²⁰, in terms of orbit evolution during the red giant phase, the situation is less clear. There are at least two competing processes which deter-

mine the orbital evolution: mass loss from the star that causes the orbit of a planet to expand, and tidal effects that tend to reduce its angular momentum causing spiralling-in²¹. Both the stellar mass loss and the tidal dissipation are not well known. For this reason, even the destiny of our Earth is matter of debate^{4,5}. For V 391 Peg b the most likely scenario is that the planet never entered the stellar envelope (the maximum radius expected for an sdB progenitor at the tip of the red giant branch is of the order of 0.7 AU^{22,23}) and that, due to the strong mass loss of the parent star, the orbit of V 391 Peg b was tighter in the past, with an orbital radius of about 1 AU when the star was still on the main sequence. This value is obtained assuming that the stellar mass has been reduced from 0.85 to 0.5 M_⊙, when tidal interaction (which is proportional to $(R_*/r)^8$)²⁴ can be neglected for a sufficiently large orbital distance r with respect to the stellar radius R_{*}. In this scenario the increase of the planet's mass due to accretion from the stellar wind is negligible²⁰. Note that in this case, incidentally, the orbital distances of V 391 Peg b and of the Earth, before and after the red giant phase, are very similar: 1.5 AU is a reasonable value for the Earth after red giant migration, when tidal effects are not considered^{4,5}.

A different scenario is obtained if the mass loss of the red giant precursor of V 391 Peg started sufficiently late: in this case the ratio between stellar

radius and orbital distance could have reached a value of about 0.7, at which the star fills its Roche lobe²⁵ and mass transfer to the planet starts, causing the planet to quickly spiral into the outer layers of the giant's atmosphere. Here accretion is disrupted and the spiral-in due to accretion stops, so that the planet may have survived if the spiral-in due to friction was sufficiently low. The presence of planets with orbital separations $\lesssim 5$ AU has been invoked by a few authors to explain the strong mass loss needed to form sdB stars and partially explain the irregular morphology of the horizontal branch²⁶.

Author Contributions

R.S. analysed and interpreted the data from which the presence of the planet was inferred. R.S., S.S., R.J., J.-E.S., S.B., R.Ø., T.D.O., I.B., R.G., A.Bo., G.V., M.R., C.-W.C., E.L. and M.P. contributed to the large amount of observations and/or data reduction. A.Ba., S.C., N.D., S.K., D.K., P.M., R.R. and S.Z. contributed to the organization and/or on-line data reduction/analysis during the XCov23 Whole Earth Telescope campaign of August-September 2003, in which V 391 Peg was observed as a secondary target. S.K. performed

some tests on theoretical \dot{P} . S.K. and S.Z. did independent checks of the O–C fits. E.L. made statistical tests on the significance level of the O–C fits. All authors discussed and interpreted the results and commented on the manuscript. D.K. and R.Ø. gave a particular help on improving the text.

Table 1 | Orbital parameters

Orbital period, P_{ORB} [d]	$1,170 \pm 44$
Epoch of max time delay, T_0 [BJD]	$2,452,418 \pm 96$
Eccentricity, e (assumed)	0.0
Star projected orbital radius, $a_s \sin i$ [km]	$1,600,000 \pm 190,000$
Star projected orbital velocity, $v_s \sin i$ [m s^{-1}]	99 ± 12
Mass function ^a $f(M_1, M_2)$ [M_\odot]	$(1.19 \pm 0.43) \times 10^{-7}$
Distance from the star ^b , a [AU]	1.7 ± 0.1
Maximum elongation ^b [milliarcsec]	1.2 ± 0.1
Planet orbital velocity ^b , v_p [km s^{-1}]	16 ± 1
Planet mass ^b , $M_2 \sin i$ [M_{JUP}]	3.2 ± 0.7

^a $f(M_1, M_2) = 4\pi^2 (a_s \sin i)^3 / G P_{\text{ORB}}^2 = (M_2 \sin i)^3 / (M_1 + M_2)^2$

^b These numbers are obtained assuming $M_1 = 0.5 \pm 0.05 M_\odot$ (suggested from astero-seismology) and $M_2 \ll M_1$.

Figure 1 | The O–C diagram of the main pulsation frequency (f_1) of V 391 Pegasi.

The O–C (Observed – Calculated) technique is a way to measure the phase variations of a periodic function comparing the observed times of the maxima with those calculated from an ephemeris¹². In our case, what is compared is the time of the first maximum of each single run (obtained by fitting the data with 5 sinusoids simultaneously, corresponding to the 5 pulsation frequencies) with the best ephemeris obtained fitting the whole (7-yr long) data set. The error bars are given by $(\sigma_O^2 + \sigma_C^2)^{1/2}$, where σ_O and σ_C are the 1σ phase errors obtained from the least-squares sinusoidal fits. Upper panel: the fit of the long-term component by means of a second-order polynomial is significantly improved when we also use a sine wave. Fitting the data with both functions simultaneously reduces the value of the reduced χ^2 from 14.1 (second-order polynomial alone) to 2.7. Lower panel: the sinusoidal component alone. To obtain these plots, 418 hr of time-series photometry from 167 nights of observation were used, from 18 different 1-m to 3-m class telescopes (see online Supplementary Information for more details). The number of photometric measurements for each point varies from 237 (the highest point with large error bar) to 26,081 (the first point on the left). In total, the number of photometric measurements is 109,531. The data were reduced following stan-

dard procedures for time-series photometry, using statistical weights²⁷ and barycentric time corrections²⁸ (BJD stands for barycentric Julian day). One second was added to the data of 2006 only, to compensate for the leap second correction of 1 January 2006. Looking at the time distribution of the phase measurements, we note that there are seven groups of close points corresponding to the seven observing seasons (from May to December) of the last seven years (2000 to 2006).

Figure 2 | The O–C diagram of f_1 .

In this version of the O–C diagram, all the runs of each observing season were joined and the phases were recalculated on these larger data sets. This reduces the noise (but also reduces the time resolution), so that in principle O–C diagrams can be built for each pulsation frequency of a multiperiodic pulsator. In this way, if the pulsating star has a companion, each pulsation mode can supply an independent confirmation of the periodic motion around the centre of mass. V 391 Peg has four or five pulsation periods; for two of them that have sufficiently large amplitudes of 1% and 0.4% respectively, O–C diagrams can be obtained. As in Fig. 1, the upper and lower plots represent respectively the O–C diagram of f_1 and its sinusoidal component alone. The error bars are calculated as in Fig. 1.

Figure 3 | The O–C diagram of f_2 .

Same as Fig. 2 but relative to the second pulsation frequency (f_2). Comparing the lower panels of Figs 2 and 3, we see that the two sinusoids of f_1 and f_2 are identical within the errors. The agreement between periods, amplitudes and phases is always better than 0.2σ . We obtain respectively $1,174 \pm 94$ versus $1,194 \pm 106$ d, 5.9 ± 1.6 versus 6.0 ± 2.3 s, and BJD $2,452,443 \pm 194$ versus $2,452,471 \pm 211$ for the epoch of the first maximum. From the second-order polynomial component of the fit in the upper panel, we obtain also a measurement of the secular variation of f_2 : $\dot{P}_2 = (2.05 \pm 0.26) \times 10^{-12}$, which is different from $\dot{P}_1 = (1.46 \pm 0.07) \times 10^{-12}$. The absolute values of \dot{P}_1 and \dot{P}_2 , that correspond to an evolutionary timescale P/\dot{P} of 7.6×10^6 and 5.5×10^6 yr respectively, match relatively well with theoretical expectations for evolved models of extreme horizontal branch stars²⁹ (even though their positive sign is more difficult to explain and suggests that the star is expanding, as confirmed by some tests done by one of us). Note that the difference between \dot{P}_1 and \dot{P}_2 excludes the possibility that the long-term component of the O–C plots is due to a secondary planet with a larger orbit.
